10
11  /*
12   * The threads implementation uses the rfork(RFPROC|RFTHREAD|RFMEM) syscall
13   * to create threads.  All threads use the stacks of the same size mmap()ed
14   * below the main stack.  Thus the current thread id is determined via
15   * the stack pointer value.
16   *
17   * The mutex implementation uses the ngx_atomic_cmp_set() operation
18   * to acquire a mutex and the SysV semaphore to wait on a mutex and to wake up
19   * the waiting threads.  The light mutex does not use semaphore, so after
20   * spinning in the lock the thread calls sched_yield().  However the light
21   * mutexes are intended to be used with the "trylock" operation only.
22   * The SysV semop() is a cheap syscall, particularly if it has little sembuf's
23   * and does not use SEM_UNDO.
24   *
25   * The condition variable implementation uses the signal #64.
26   * The signal handler is SIG_IGN so the kill() is a cheap syscall.
27   * The thread waits a signal in kevent().  The use of the EVFILT_SIGNAL
28   * is safe since FreeBSD 4.10-STABLE.
29   *
30   * This threads implementation currently works on i386 (486+) and amd64
31   * platforms only.

13   * The code and lookup tables are based on the algorithm
14   * described at http://www.w3.org/TR/PNG/
15   *
16   * The 256 element lookup table takes 1024 bytes, and it may be completely
17   * cached after processing about 30-60 bytes of data.  So for short data
18   * we use the 16 element lookup table that takes only 64 bytes and align it
19   * to CPU cache line size.  Of course, the small table adds code inside
20   * CRC32 loop, but the cache misses overhead is bigger than overhead of
21   * the additional code.  For example, ngx_crc32_short() of 16 bytes of data
22   * takes half as much CPU clocks than ngx_crc32_long().
